ABSTRACT

We study global non-axisymmetric oscillation modes trapped near the inner boundary of an accretion disc. Observations indicate that some of the quasi-periodic oscillations (QPOs) observed in the luminosities of accreting compact objects (neutron stars, black holes and white dwarfs) are produced in the inner-most regions of accretion discs or boundary layers. Two simple models are considered in this paper: The magnetosphere-disc model consists of a thin Keplerian disc in contact with a uniformly rotating magnetosphere with low plasma density, while the star-disc model involves a Keplerian disc terminated at the stellar atmosphere with high density and small density scale height. We find that the interface modes at the magnetosphere-disc boundary are generally unstable due to Rayleigh-Taylor and/or Kelvin-Helmholtz instabilities. However, differential rotation of the disc tends to suppress Rayleigh-Taylor instability and a sufficiently high disc sound speed (or temperature) is needed to overcome this suppression and to attain net mode growth. On the other hand, Kelvin-Helmholtz instability may be active at low disc sound speeds. We also find that the interface modes trapped at the boundary between a thin disc and an unmagnetized star do not suffer Rayleigh-Taylor or Kelvin-Helmholtz instability, but can become unstable due to wave leakage to large disc radii and, for sufficiently steep disc density distributions, due to wave absorption at the corotation resonance in the disc. The non-axisymmetric interface modes studied in this paper may be relevant to the high-frequency QPOs observed in some X-ray binaries and in cataclysmic variables.

1 INTRODUCTION

Quasi-periodic variabilities have been observed in the timing data of various types of accreting objects. Several types of quasi-periodic oscillations (QPOs) are observed in X-ray binaries with accreting black holes (BHs) or neutron stars (NSs) (e.g., Remillard & McClintock 2006; Van der Klis 2006). Oscillations are also seen in the outbursts of accreting white dwarf (WD) systems (e.g., Patterson 1981; see Warner 2004 for a review).

In accreting NS and BH X-ray binaries the observed QPO frequencies (40 – 450 Hz for the high-frequency QPOs in the BH systems and $\gtrsim 300$ Hz for kHz QPOs in the NS systems) imply a source close to the central compact object where the Keplerian orbital frequencies are high. Since the BH systems lack a hard surface where oscillations may occur, it is likely that the source of the variability is in the inner regions of the disc itself or in some interface regions between the disc and the plunging flow. Gilfanov et al (2003), however, found that, based on spectral analysis of the disc emission components, the quasi-periodic variability in Low Mass NS X-ray Binary systems are most likely caused by variations in the disc boundary layer, rather than the disc itself.

In Cataclysmic Variables (CVs) the Dwarf Nova Oscillations (DNOs) seen during outbursts have frequencies roughly corresponding to the Keplerian rotation rate at the WD surface (e.g., Patterson, 1981; Warner, 2004; Knigge et al, 1998), which imply an origin at or near the inner disk boundary.

Several models involving accretion disk boundary dynamics have been proposed in different contexts. Popham (1999) studied the effect of a non-axisymmetric bulge at the optically thick to optically thin transition radius as a model for DNOs. Piro & Bildsten (2004) examined the surface wave oscillations that would occur within the thin equatorial belt around a

non-magnetized WD formed by the accretion spreading layer, while Warner & Woudt (2002) considered accretion onto a slipping belt. In the context of accreting magnetic (neutron) stars, Arons & Lea (1976) and Elsner & Lamb (1977) considered the interchange instability at the magnetosphere boundary. Spruit & Taam (1990) and Spruit, Stehle & Papaloizou (1995) investigated the stability of thin rotating magnetized discs. Of particular relevance to the present paper is the work of Li & Narayan (2004), who examined a simplified cylindrical model of the Rayleigh-Taylor and Kelvin-Helmholtz instabilities at the boundary between a magnetosphere and an incompressible rotating flow. There have also been a number of numerical simulations of the interface at the magnetosphere-disc boundary (see Romanova et al., 2008 and Kulkarni & Romanova, 2008 and references therein).

In this paper we study global non-axisymmetric oscillation modes confined near inner boundary of the accretion disc (interface modes). We consider two simple models. The first model involves the magnetosphere-disc boundary similar to the model of Li & Narayan (2004): we consider an uniformly rotating incompressible magnetosphere with low gas density (where magnetic pressure dominates), which truncates a thin barotropic accretion disc (where gas pressure dominates). This situation may arise from magnetic field build up due to accretion (e.g., Bisnovatyi-Kogan & Ruzmaikin, 1974, 1976; Igumenshchev et al., 2003; Rothstein & Lovelace, 2008) or by the magnetosphere of a central (neutron) star. Unlike Li & Narayan (2004), who restricted their model to incompressible fluid, our discs are compressible and we show that because of the differential rotation of the disc, finite disc sound speed plays an important role in the development of the instability of the interface modes.

In our second model we examine the interface modes for accretion onto a non-magnetic stellar surface. Though the structure of the boundary layer is non-trivial and may affect boundary modes (see, e.g., Carroll et al., 1985; Collins et al., 2000), we consider the instabilities for a thin disc truncated by a sharp transition to a dense uniformly rotating stellar atmosphere. This simplified model may provide insight for modes with characteristic radial length scale much greater than the radial length scale of the boundary layer.

In Section 2 we describe the basic setup for the magnetospheric boundary model, and in Section 3 we discuss the resulting interface mode instabilities. We describe the star-disc boundary and analyze its possible instabilities in Section 4. We then conclude in Section 5 with a discussion of possible applications of our findings.

2 MAGNETOSPHERE-DISC SETUP

We begin by considering a simplified model of the magnetosphere-disc boundary similar to the one considered by Li & Narayan (2004). The magnetic field is assumed to be negligible in the disc region ($r > r_{\text{in}}$), while the magnetosphere region ($r < r_{\text{in}}$) is assumed to be incompressible and have low density compared to the disc region, with purely vertical magnetic field. Unlike Li & Narayan (2004), who assumed infinite sound speed in the disc, our disc has sound speed c_s much less than the disk rotation speed $r\Omega$.

In terms of the vertically integrated density (Σ), pressure (P), magnetic field ($\mathbf{B}$) and fluid velocity ($\mathbf{u}$) the ideal MHD equations are:

$$\frac{\partial \Sigma}{\partial t} + \nabla \cdot (\Sigma \mathbf{u}) = 0 \quad (1)$$

$$\frac{\partial \mathbf{u}}{\partial t} + (\mathbf{u} \cdot \nabla) \mathbf{u} = -\frac{1}{\Sigma} \nabla \Pi - \nabla \Phi + \frac{1}{\Sigma} \mathbf{T} \quad (2)$$

$$\frac{\partial \mathbf{B}}{\partial t} = \nabla \times (\mathbf{u} \times \mathbf{B}). \quad (3)$$

where $\Pi \equiv P + B^2/8\pi$ is the total pressure, $\mathbf{T} = \frac{1}{4\pi}(\mathbf{B} \cdot \nabla) \mathbf{B}$ is the magnetic tension, and Φ is the gravitational potential due to the central object (e.g. Fu & Lai, 2008). Using cylindrical coordinates (r, ϕ, z) , we consider the case where the magnetic field is purely poloidal and $\mathbf{B} = B_z \hat{z}$ in the disc plane, which gives $\mathbf{T} = 0$. We assume an axisymmetric background flow with fluid velocity $\mathbf{u} = r\Omega(r)\hat{\phi}$. The unperturbed flow satisfies the condition

$$g_{\text{eff}} \equiv -\frac{1}{\Sigma} \frac{d\Pi}{dr} = \frac{d\Phi}{dr} - \Omega^2 r. \quad (4)$$

The linearized equations of (1) and (2) with perturbations of the form $e^{im\phi - i\omega t}$ (assuming no vertical dependence) take the form:

$$-i\tilde{\omega}\delta\Sigma + \frac{1}{r} \frac{\partial}{\partial r} (\Sigma r \delta u_r) + \frac{im\Sigma}{r} \delta u_\phi = 0, \quad (5)$$

$$-i\tilde{\omega}\delta u_r - 2\Omega\delta u_\phi = -g_{\text{eff}} \frac{\delta\Sigma}{\Sigma} - \frac{1}{\Sigma} \frac{\partial}{\partial r} \delta\Pi, \quad (6)$$

$$-i\tilde{\omega}\delta u_\phi + \frac{\kappa^2}{2\Omega} \delta u_r = -\frac{im}{\Sigma r} \delta\Pi, \quad (7)$$

where $\tilde{\omega} = \omega - m\Omega$ is the Doppler shifted frequency, $\kappa = \left[\frac{2\Omega}{r} \frac{d}{dr}(r^2\Omega)\right]^{1/2}$ is the radial epicyclic frequency, and $\delta\Sigma$, $\delta\Pi$ and $\delta\mathbf{u}$ are the Eulerian perturbations of the fluid variables. Additionally, assuming a barotropic flow we have

Figure 1. The wavefunctions for the interface mode for $m = 4$, $c_s = 0.1r\Omega$, $\Sigma_-/\Sigma_+ = 1/99$ and $\Omega_-/\Omega_{\text{in}} = 1$, with the mode frequency $\omega/\Omega_{\text{in}} = 4.275 + 0.1914i$, where $\Omega_{\text{in}} \equiv \Omega(r_{\text{in}+}) \simeq \Omega_k(r_{\text{in}})$. The real components are shown in solid lines, while the imaginary components are dashed lines. Note that for the interface modes only the outer Lindblad resonance (r_{OL} , denoted by the dotted line) exists outside r_{in}

$$\delta\Sigma = \frac{1}{c_s^2}\delta P = \frac{1}{c_s^2}(\delta\Pi - \frac{1}{4\pi}\mathbf{B} \cdot \delta\mathbf{B}) . \quad (8)$$

with the sound speed $c_s \equiv (dP/d\Sigma)^{1/2}$.

2.1 The Magnetosphere

In the inner, magnetically dominated region ($r < r_{\text{in}}$), we assume the flow to be incompressible, and have uniform rotation ($\Omega = \Omega_- = \text{const}$) and uniform surface density ($\Sigma = \Sigma_- = \text{const}$). Equations (5) - (7) then reduce to

$$\frac{1}{r} \frac{\partial}{\partial r} (\Sigma r \delta u_r) + \frac{im\Sigma}{r} \delta u_\phi = 0 \quad (9)$$

$$-i\tilde{\omega}\delta u_r - 2\Omega\delta u_\phi = -\frac{1}{\Sigma} \frac{\partial}{\partial r} \delta\Pi \quad (10)$$

$$-i\tilde{\omega}\delta u_\phi + \frac{\kappa^2}{2\Omega}\delta u_r = -\frac{im}{\Sigma r} \delta\Pi, \quad (11)$$

As in Li & Narayan (2004) we define $W \equiv r\delta u_r$ and find $\delta u_\phi = (i/m)dW/dr$ and

$$\frac{1}{r} \frac{d}{dr} \left(r \frac{dW}{dr} \right) - \frac{m^2}{r^2} \left[1 - \frac{r}{m\tilde{\omega}} \frac{d}{dr} \left(\frac{\kappa^2}{2\Omega} \right) \right] W = 0 . \quad (12)$$

For uniform rotation, $\kappa = 2\Omega$, equation (12) has the solution $W \propto r^{\pm m}$. Since $r < r_{\text{in}}$, we take the positive sign to be the physical solution so that the perturbation falls off away from the interface. Thus the exact solution for the $r < r_{\text{in}}$ region is

$$\delta u_r = \delta u_r(r_{\text{in}}) \left(\frac{r}{r_{\text{in}}} \right)^{m-1} . \quad (13)$$

2.2 The Disc

In the disc ($r > r_{\text{in}}$), we take the magnetic field to be small, such that $P \gg B^2/(8\pi)$, and the angular velocity of the unperturbed flow to be nearly Keplerian, such that $\Omega(r) \approx \Omega_k(r) \equiv \sqrt{\frac{1}{r} \frac{d\Phi}{dr}}$. Rewriting equations (5) - (7) we have

$$-i\tilde{\omega} \frac{\Sigma}{c_s^2} \delta h + \frac{1}{r} \frac{\partial}{\partial r} (\Sigma r \delta u_r) + \frac{im\Sigma}{r} \delta u_\phi = 0 , \quad (14)$$

$$-i\tilde{\omega}\delta u_r - 2\Omega\delta u_\phi = -\frac{\partial}{\partial r}\delta h, \quad (15)$$

$$-i\tilde{\omega}\delta u_\phi + \frac{\kappa^2}{2\Omega}\delta u_r = -\frac{im}{r}\delta h, \quad (16)$$

where

$$\delta h \equiv c_s^2 \frac{\delta \Sigma}{\Sigma} = \frac{\delta P}{\Sigma} \quad (17)$$

is the enthalpy perturbation. Eliminating the velocity perturbations in favor of the enthalpy, we obtain the second order ODE for the enthalpy perturbation in the disc,

$$\left[\frac{d^2}{dr^2} - \frac{d}{dr} \left(\ln \frac{D}{r\Sigma} \right) \frac{d}{dr} - \frac{2m\Omega}{r\tilde{\omega}} \left(\frac{d}{dr} \ln \frac{\Omega\Sigma}{D} \right) - \frac{m^2}{r^2} - \frac{D}{c_s^2} \right] \delta h = 0. \quad (18)$$

where $D \equiv \kappa^2 - \tilde{\omega}^2$. For concreteness we will assume a power-law disc surface density profile $\Sigma \propto r^{-p}$.

2.3 Matching Conditions Across the Interface

The matching conditions across the interface at r_{in} between the magnetosphere and the disc region are given by demanding the continuity of the Lagrangian displacement in the radial direction $\xi_r = i\delta u_r/\tilde{\omega}$, and the total Lagrangian pressure perturbation $\Delta\Pi = \delta\Pi + \xi_r \frac{d\Pi}{dr}$ across the boundary. The former gives

$$\frac{i\delta u_{r+}}{\tilde{\omega}_+} = \frac{i\delta u_{r-}}{\tilde{\omega}_-}, \quad (19)$$

where the subscript “ $\pm$ ” implies that the quantities are evaluated at $r = r_{\text{in}\pm}$. The total Lagrangian pressure perturbation for $r = r_{\text{in-}}$ is given by

$$\begin{aligned} \Delta\Pi_- &= \Sigma_- \left[\left(\frac{i\kappa^2}{2m\Omega} + \frac{i}{r\tilde{\omega}} \frac{d\Pi}{dr} \right) W + \frac{ir\tilde{\omega}}{m^2} \frac{dW}{dr} \right]_{r_{\text{in-}}} \\ &= \Sigma_- \left[\frac{2r\Omega\tilde{\omega}}{m} - g_{\text{eff}} + \frac{r\tilde{\omega}^2}{m} \right] \frac{i\delta u_r}{\tilde{\omega}} \Big|_{r_{\text{in-}}}. \end{aligned} \quad (20)$$

In the disc region, we have

$$\begin{aligned} \Delta\Pi_+ &= \Delta P_+ = \Sigma_+ \left(\delta h + \frac{i\delta u_r}{\tilde{\omega}} \frac{1}{\Sigma} \frac{dP}{dr} \right)_{r_{\text{in+}}} \\ &= \Sigma_+ \left(\frac{\tilde{\omega}\delta h}{i\delta u_r} - \frac{pc_s^2}{r} \right) \frac{i\delta u_r}{\tilde{\omega}_+} \Big|_{r_{\text{in+}}}. \end{aligned} \quad (21)$$

The condition $\Delta\Pi_+ = \Delta\Pi_-$ then gives

$$\Sigma_+ \left(\frac{\tilde{\omega}\delta h}{i\delta u_r} - \frac{pc_s^2}{r} \right)_{r_{\text{in+}}} = \Sigma_- \left(\frac{2r\Omega\tilde{\omega}}{m} - g_{\text{eff}} + \frac{r\tilde{\omega}^2}{m} \right)_{r_{\text{in-}}}. \quad (22)$$

3 INTERFACE MODES AT THE MAGNETOSPHERE-DISC BOUNDARY

Perturbations mainly confined to the magnetosphere-disc interface can become unstable due to Rayleigh-Taylor or Kelvin-Helmholtz instability. In order to calculate the growth rates, we must solve the eigenvalue problem given by equation (18) with an outgoing wave boundary condition at some outer radius, and equation (22) at the interface radius r_{in} .

3.1 Numerical Solution

We adopt the radiative outer boundary condition in the outer wave zone of the disc, such that far from the outer Lindblad resonance radius r_{OL} (where $\omega - m\Omega = \kappa$) we have the solution of the form:

$$\delta h \propto A \exp \left(i \int^r k dr \right), \quad (23)$$

with $A = (D/r\Sigma k)^{1/2}$ and $k = (-D/c_s^2)^{1/2}$ (see Tsang & Lai 2008, Lai & Tsang, 2008). This gives the boundary condition at $r = r_{\text{out}} > r_{\text{OL}}$:

Figure 2. Real and imaginary frequencies for interface modes for various m as a function of the disc sound speed c_s . The left panels are for $\Sigma_-/\Sigma_+ = 0$, while the right panels are for $\Sigma_-/\Sigma_+ = 1/9$, both with $\Omega_-/\Omega_{\text{in}} = 1$. The solid lines show the eigenfrequencies for $m = 5$ modes, the dash-dotted lines for $m = 4$, the long-dashed lines for $m = 3$, the short-dashed lines for $m = 2$, and the dotted lines for $m = 1$.

Figure 3. Same as Figure 2, except that the left panels are for $\Sigma_-/\Sigma_+ = 1/99$, while the right panels are for $\Sigma_-/\Sigma_+ = 1/9$, both with $\Omega_-/\Omega_{\text{in}} = 0.5$.

$$\delta h'(r_{\text{out}}) = \delta h(r_{\text{out}}) \left(ik + \frac{1}{A} \frac{dA}{dr} \right)_{r_{\text{out}}}. \quad (24)$$

We adopt (22) as the inner boundary condition for the disc and solve the eigenvalue problem using a standard shooting method (Press et al 1998). For the numerical solutions below, the density profile of the disc was assumed to be $\Sigma \sim r^{-3/2}$ so

that corotation absorption plays no role in determining the mode stability (Tsang & Lai 2008). An example wavefunction for an interface mode is shown in Figure 1, for typical disc parameters.

The numerical eigenvalues are shown in Figure 2 and Figure 3 for various disc and magnetosphere parameters, for $m = 1, 2, \dots, 5$.

3.2 Discussion of Numerical Results

Figure 2 shows the complex eigenvalues as a function of sound speed c_s , for density contrasts corresponding to $\Sigma_- = 0$ and $\Sigma_- = \frac{1}{9}\Sigma_+$, with magnetosphere rotation rate equal to the Kepler frequency at the interface [$\Omega_- = \Omega(r_{\text{in}+}) \simeq \Omega_k(r_{\text{in}})$]. For this case we see that there exists a cutoff in the disc sound speed below which no growing interface modes are found. This arises from the stabilizing effect of the background differential rotation, and can be understood as follows.

Setting $\Sigma_- = 0$ and rewriting (22) in terms of the radial velocity perturbation δu_r , we have:

$$\zeta_+ \tilde{\omega} + \frac{\tilde{\omega}^2}{m \Sigma_+ \delta u_r} \frac{d}{dr} (\Sigma_+ r \delta u_r) + g_{\text{eff}+} \left(\frac{r \tilde{\omega}^2}{m c_s^2} - \frac{m}{r} \right) = 0 \quad (25)$$

where $g_{\text{eff}+} = p c_s^2 / r$ [see Eq. (4)] and $\zeta \equiv \kappa^2 / (2\Omega)$ is the vorticity, and where all quantities are evaluated at the interface $r_{\text{in}+}$. For the wave frequencies of interest, the waves are evanescent in the region of the disk just outside the interface. Let $\tilde{k} \equiv -\delta u_r' / \delta u_r > 0$. Equation (25) can be solved in terms of $\tilde{k}$, giving

$$\tilde{\omega} = \frac{m \zeta}{2\gamma} \pm i \sqrt{\frac{g_{\text{eff}+} m^2}{r \gamma} - \frac{m^2 \zeta^2}{4\gamma^2}} \quad (26)$$

where $\gamma \equiv \tilde{k} r - 1$. The terms inside the square root correspond to the mode growth due to Rayleigh-Taylor instability and the suppression due to vorticity, respectively. With $g_{\text{eff}+} = p c_s^2 / r$ we find the critical sound speed

$$c_{\text{crit}} \approx \sqrt{\frac{\zeta^2 r^2}{4p\gamma}}, \quad (27)$$

above which the perturbations will be unstable.

Figure 3 shows cases where the inner region is uniformly rotating at an angular frequency of one half the Kepler frequency at the interface [$\Omega_- = 0.5\Omega(r_{\text{in}+})$]. When $\Sigma_- > 0$ this leads to the development of the Kelvin-Helmholtz instability, and both this and the Rayleigh-Taylor instability play a role in the mode growth. In the Appendix we derive the expression for the plane-parallel Rayleigh-Taylor and Kelvin-Helmholtz instabilities for a compressible upper region (with density ρ_+ and horizontal velocity u_+), and incompressible lower region (with density ρ_- and horizontal velocity u_-). For $\rho_- \ll \rho_+$ we have $\omega \approx k u_+ \pm i \omega_i$ where k is the horizontal wavenumber and

$$\omega_i = \sqrt{k \tilde{k} (u_+ - u_-)^2 \left(\frac{\rho_-}{\rho_+} \right) + g \tilde{k}} \equiv \sqrt{\omega_{\text{KH}}^2 + \omega_{\text{RT}}^2}. \quad (28)$$

Here $\tilde{k} \approx \frac{1}{2H_z} [\sqrt{1 + H_z^2 k^2} - 1]$, g is the acceleration due to gravity in the vertical direction, and H_z is the vertical scale height in the upper region. The Kelvin-Helmholtz term is approximately

$$\omega_{\text{KH}}^2 \approx k \tilde{k} (u_+ - u_-)^2 \left(\frac{\rho_-}{\rho_+} \right). \quad (29)$$

For $k H_z \gg 1$ this reduces to the incompressible limit with $\omega_{\text{KH}}^2 \approx k^2 (u_+ - u_-)^2 \rho_- / \rho_+$. For $k H_z \ll 1$ we have $\omega_{\text{KH}}^2 \approx (H_z k)^2 k^2 (u_+ - u_-)^2 \rho_- / \rho_+$, a factor of $H_z k$ smaller than the incompressible result.

For the rotating system under consideration, the imaginary part of the mode frequency can be written schematically as [cf. equation (28)]

$$\omega_i \approx \sqrt{\omega_{\text{KH}}^2 + \omega_{\text{RT}}^2 + \omega_{\text{vort}}^2}. \quad (30)$$

We also have $H_z \sim c_s^2 / g_{\text{eff}} \sim r$ and $k \sim m / r$ so $k H_z \sim m$. Thus $\omega_{\text{KH}}^2 \sim (\Delta\Omega)^2 \Sigma_- / \Sigma_+$, and ω_{KH}^2 depends weakly on sound speed. On the other hand, from equation (26) we see that the vorticity suppresses mode growth through the term $\omega_{\text{vort}}^2 = -m^2 \zeta^2 / (4\gamma^2)$. For sufficiently small c_s , equation (18) indicates $\delta h \propto e^{-\kappa r / c_s}$, i.e. $\tilde{k} \sim \kappa / c_s$. Therefore the vorticity term scales with sound speed as $\omega_{\text{vort}}^2 \sim -m^2 c_s^2 / r^2$, and can be dominated by the Kelvin-Helmholtz term for small enough sound speed. In the left panel of Figure 3, the mode growth ($\omega_i > 0$) for small c_s is mainly driven by the Kelvin-Helmholtz instability. For $m \geq 5$ the sound speed ranges where ω_{RT}^2 and ω_{KH}^2 dominate over ω_{vort}^2 overlap, and hence the critical sound speed in equation (27) is not relevant. For larger values of Σ_- these regions can overlap for all m .

Figure 4. Real and imaginary frequencies for the interface modes of various m (denoted as in Figure 2) as a function of sound speed c_s with $r_{\text{in}} = r_{\text{ISCO}}$ for the pseudo-newtonian GR potential. There is no sound speed cutoff for unstable modes as the vorticity is zero at the interface. The left panels show the eigenvalues for $\Sigma_- = 0$ and $\Omega_- = \Omega(r_{\text{in}+})$ and the right panel shows the eigenvalues for $\Sigma_- = \frac{1}{99}\Sigma_+$ and $\Omega_- = 0.5\Omega_{\text{in}}$.

3.3 Effect of a Relativistic Potential

While in Section 3.2 and other sections of the paper we focus on Newtonian discs, it is of interest to consider how general relativity may modify our results. The effect of general relativity can be approximated by using the pseudo-Newtonian Paczynski & Wiita (1980) potential:

$$\Phi = -\frac{GM}{r - r_S}, \quad (31)$$

with $r_S = 2GM/c^2$ the Schwarzschild radius. This gives the Keplerian orbital frequency (Ω_k) and epicyclic frequency (κ) as:

$$\Omega_k = \left(\frac{1}{r} \frac{d\Phi}{dr} \right)^{1/2} = \sqrt{\frac{GM}{r} \frac{1}{r - r_S}}, \quad \kappa = \left[\frac{2\Omega_k}{r} \frac{d}{dr} (r^2 \Omega_k) \right]^{1/2} = \Omega_k \sqrt{\frac{r - 3r_S}{r - r_S}}. \quad (32)$$

with $\kappa \rightarrow 0$ at $r_{\text{ISCO}} = 3r_S = 6GM/c^2$.

For $r_{\text{in}} \gg r_{\text{ISCO}}$ the interface modes are the same as for the Newtonian case. However, as $r_{\text{in}} \rightarrow r_{\text{ISCO}}$ the suppression effect of ω_{vort}^2 [see Eq. (26)] is reduced as the vorticity goes to zero at r_{ISCO} , so that for $r_{\text{in}} = r_{\text{ISCO}}$ there is no cutoff sound speed (see Figures 2-3) for interface mode instability. This is illustrated in Figure 4. Thus if the magnetosphere boundary is at r_{ISCO} , the interface modes will always be present and highly unstable for any sound speed.

3.4 P-modes with Magnetosphere Boundary

The boundary condition given by equation (22) also provides an inner reflection boundary for disc p-modes, which were studied in detail in Lai & Tsang (2008). These modes have wavefunctions primarily “trapped” in the wave region between the disc boundary r_{in} and the inner Lindblad resonance radius, r_{LR} , where $\omega - m\Omega = -\kappa$. Figure 5 depicts an example of the p-mode wave function for the same disc model as in Figure 1. The growth rates of these p-modes are determined primarily by the outgoing flux at the outer boundary and the effect of the corotation resonance, as discussed in Lai & Tsang (2008). In Figure 6 the eigenfrequencies are shown for p-modes in a disc with the density profile $\Sigma \propto r^{-p}$, where $p = 3/2$ so that wave absorption at the corotation resonance is inactive (since in this case the vortensity $\kappa^2/(2\Omega\Sigma)$ is constant). For the density profile $p < 3/2$, the corotation absorption tends to damp the mode, while for $p > 3/2$ the corotation absorption enhances it.

Figure 5. The p-mode wavefunctions for $m = 4$, $c_s = 0.1r\Omega$, $\Sigma_-/\Sigma_+ = 1/99$, $\Omega_-/\Omega_+ = 1$ with $\omega/\Omega_{\text{in}} = 1.914 + 0.000127i$. The real components are shown in solid lines, while the imaginary components are dashed lines. For p-modes the inner and outer Lindblad resonances and the corotation resonance are outside r_{in} , denoted by the dotted lines.

4 INTERFACE MODES AT THE STAR-DISC BOUNDARY

4.1 Star-Disc Boundary Condition

In the case of accretion on to a non-magnetic star, our model consists of a dense uniformly rotating compressible stellar atmosphere truncating the accretion disc. This model ignores the structure of the boundary layer. However the qualitative properties of the dynamics should be captured for modes with characteristic radial length scale much greater than the radial scale of the boundary layer.

Several studies of CVs (e.g. by examining the rotationally broadened line emissions from the stellar surface) have shown that the stellar rotation rates are significantly below the breakup rotation rate (see Warner, 2004), and we limit our examinations to systems with $|\Omega_-| \leq 0.5\Omega(r_{\text{in}+})$. As in the case of the disc, we consider only the effect of perturbations on a cylindrical equatorial surface of the stellar atmosphere (i.e., we are considering a "cylindrical" star). In this region equation (18) also describes the enthalpy perturbations within the stellar atmosphere. Inside the atmosphere, we assume a small constant density scale height, $-\Sigma/\Sigma' \equiv H_\Sigma \ll r$. Equation (18) then becomes

$$\delta h'' - \frac{1}{H_\Sigma} \delta h' - \left(\frac{2m\Omega}{r\tilde{\omega}H_\Sigma} + \frac{D}{c_s^2} \right) \delta h \approx 0. \quad (33)$$

For $H_\Sigma \ll r$ and $H_\Sigma \ll c_s/\Omega$, this has the solution

$$\delta h \propto \exp[(r - r_{\text{in}})/H_\Sigma]. \quad (34)$$

The Lagrangian pressure perturbation at the stellar surface is then

$$\begin{aligned} \Delta P_- &= \Sigma_- \left[\frac{\tilde{\omega}\delta h}{i\delta u_r} - r(\Omega_k^2 - \Omega^2) \right]_{r_{\text{in}-}} \frac{i\delta u_r}{\tilde{\omega}} \\ &= \left[\frac{\kappa^2 - \tilde{\omega}^2}{\frac{2\Omega m}{r\tilde{\omega}} - \frac{1}{H_\Sigma}} - r(\Omega_k^2 - \Omega^2) \right]_{r_{\text{in}-}} \Sigma_- \frac{i\delta u_r}{\tilde{\omega}}. \end{aligned} \quad (35)$$

Once again matching the Lagrangian displacement and pressure perturbation at the interface gives the boundary condition for the interface modes for the star-disc boundary case:

$$\Sigma_+ \left[\frac{\tilde{\omega}\delta h}{i\delta u_r} - \frac{pc_s^2}{r} \right]_{r_{\text{in}+}} = \Sigma_- \left[\frac{\kappa^2 - \tilde{\omega}^2}{\frac{2\Omega m}{r\tilde{\omega}} - \frac{1}{H_\Sigma}} + r(\Omega^2 - \Omega_k^2) \right]_{r_{\text{in}-}}. \quad (36)$$

Figure 6. Real and imaginary frequencies for p-modes for the magnetosphere boundary condition with $\Sigma_- = (1/99)\Sigma_+$ and $\Omega_- = 0.5\Omega_{\text{in}}$. For $\Sigma_- \ll \Sigma_+$ the p-mode frequencies have very little dependence on Ω_- . Here the disc surface density profile is chosen to be $\Sigma \propto r^{-3/2}$, so that the corotation absorption is inactive and mode growth is purely due to propagation outward at r_{out} .

4.2 Numerical Results

We repeat the numerical procedure of Section 3 using the radiative outer boundary condition [equation (24)] and using equation (36) as the inner disc boundary condition. A sample wavefunction for the star-disc interface mode is shown in Figure 7. For typical mode frequencies the region just outside the boundary is an evanescent zone; wave propagation becomes possible only beyond the outer Lindblad resonance (r_{OL}). Figure 8 shows the eigenfrequencies for the lowest order modes with $m = 1, 2, \dots, 5$ as a function of disc sound speed, for representative parameters $H_\Sigma = 0.01r_{\text{in}}$, $\Sigma_- = 10\Sigma_+$ and $\Omega_- = 0.1\Omega_+$. Figure 9 shows the dependence of the mode eigenfrequencies on the density (Σ_-), rotation rate (Ω_-), and scale height (H_Σ) of the star. We see that both the real mode frequency ω_r and the growth rate ω_i do not depend strongly on these parameters.

4.3 Discussion of Numerical Results

When the disc is truncated by the star's surface, the effective gravity acts to stabilize the perturbations (since $\Sigma_- > \Sigma_+$), as does the vorticity. Thus compared to the interface mode in the magnetosphere-disc case (Sections 3.1 – 3.2), the mode growth rates here are much smaller and are primarily driven by wave propagation through the corotation, beyond the outer Lindblad resonance. In the left panels of Figure 8 the eigenfrequencies are shown for typical parameters [$\Sigma_- = 10\Sigma_+(r_{\text{in}})$, $\Omega_- = 0.1\Omega(r_{\text{in}})$, $H_\Sigma = 0.01r_{\text{in}}$], and disc density index $p = 3/2$, so that the corotation absorption plays no role. For other density indices, wave absorption at the corotation can act to either damp or grow the interface modes (Tsang & Lai 2008; Lai & Tsang 2008). For example, in the Shakura-Sunyaev α -disc model the disc solution for the outer disc solution (with free-free opacity and gas pressure dominating) has the surface density $\Sigma \propto r^{-3/4}$, hence the modes would be stabilized by absorption at the corotation resonance. However, for models where the disc has density index $p > 3/2$ at corotation, the corotational absorption acts to enhance mode growth, as shown in the right panels of Figure 8.

The mode eigenfrequencies have very little dependence on the properties of the stellar atmosphere ($\Sigma_-, \Omega_-, H_\Sigma$), as shown in Figure 9. The mode frequencies instead primarily depend on the disc sound speed, which in turn depends on the accretion rate. Observations of CVs indicate that DNOs are usually only detected in high $\dot{M}$ states, with the oscillation period decreasing with increasing luminosity (Warner 2004). The downward trend of the $\omega_r/m\Omega_{\text{in}}$ as a function of c_s in Figure 8 would appear to contradict the observed period-luminosity anti-correlation. But note that in our model, the interface mode frequency depends on the sound speed at the inner-most disc region and boundary layer, and it will be necessary to model the thermodynamic and radiative properties of the boundary layer in order to compare with observation directly. Also, the oscillations of the type considered here would yield periods shorter than the surface Keplerian period, except for the $m = 1$ mode. Though higher- m modes would be more difficult to observe due to the averaging out of the luminosity variation, most observed DNOs, even those with 1:2:3 harmonic structure (Warner & Woudt, 2005) occur with period roughly at or greater

Figure 7. An example wavefunction for a disc/non-magnetized star interface with $m = 2$, $\Sigma_- = 10\Sigma_+$, $\Omega_- = 0.1\Omega_{\text{in}}$ and $H_\Sigma = 0.01r_{\text{in}}$ with the eigenfrequency $\omega/\Omega_{\text{in}} = 1.378 + 0.0030i$. The left side ($r < r_{\text{in}}$) of the plot denotes the perturbation eigenfunctions inside the star, while the right side shows the disc perturbations. The vertical dotted lines denote the corotation resonance radius (r_c) and the outer Lindblad resonance radius (r_{OL}).

Figure 8. The eigenfrequencies of the interface modes for the star-disc boundary for $H_\Sigma = 0.01r_{\text{in}}$, $\Sigma_- = 10\Sigma_+$ and $\Omega_- = 0.1\Omega_{\text{in}}$, as a function of disc sound speed, for $m = 1 \dots 5$. The vertically integrated surface density of the disc is given by $\Sigma_+ \propto r^{-p}$ with $p = 3/2$ for the left panels, so that corotation absorption plays no role, and $p = 2$ for the right panels, where corotation absorption acts to enhance the mode growth.

Figure 9. Eigenfrequencies for disc-star interface modes as a function of star density (Σ_-), rotation rate (Ω_-), and characteristic scale height ($\Sigma_-/\Sigma'_- = H_\Sigma$). The canonical values for various parameters are: $c_s = 0.2r_{\text{in}}\Omega_{\text{in}}$, $\Omega_- = 0.1\Omega_{\text{in}}$, $H_\Sigma = 0.01r_{\text{in}}$ and $\Sigma_- = 10\Sigma_+$.

than the corresponding surface Keplerian period. These long-period oscillations cannot be explained by the model considered here.

5 CONCLUSIONS

We have studied the non-radial oscillation modes at the interface between an accretion disc and a magnetosphere or stellar surface. Although the models explored in this paper are perhaps too simplified compared to realistic situations, they offer some insight into the behavior of the interface modes in various astrophysical contexts.

Our study of the interface modes at the magnetosphere-disc boundary extended the work by Li & Narayan (2004), who considered incompressible disc flow (and therefore could not treat real discs). The model can have very strongly unstable modes due to Rayleigh-Taylor and Kelvin-Helmholtz instabilities. In systems where the magnetosphere has developed from advection of frozen magnetic flux, the magnetosphere is expected to be roughly rotating with at the Keplerian rate. Since there is no shear at the interface, only the Rayleigh-Taylor instability may occur. However the disc vorticity (due to differential rotation) acts to suppress the instability, leading to a cutoff below a critical sound speed. Thus a sufficiently hot disc is required to generate unstable low- m modes. For magnetospheres rotating with the central star, shearing is expected between the magnetosphere and disc, and the Kelvin-Helmholtz instability becomes active. This can help to drive the instability for low- m modes to overcome the vorticity in low sound-speed discs. In discs that terminate near the ISCO in a general relativistic

potential, the vorticity approaches zero at the inner disc radius, and unstable interface modes can be found for any sound speed.

We can expect a strong dependence of the interface mode growth rates on the sound speed, and thus accretion rate, while the real frequencies of these oscillations remain close to $(1 - 1.3)m\Omega_{\text{in}}$, and do not depend strongly on the sound speed. It is worth noting that the same boundary condition that gives rise to the interface modes also gives rise to inertial-acoustic modes (or p-modes) in the disc.

Although higher- m interface modes are more unstable in our model, these are less likely to be observed due to the averaging out of the luminosity variation over the observable emitting region. In addition, if the effect of viscous damping is considered (e.g., Wang & Robertson 1985), small wavelength or high- m , perturbations are suppressed.

These results are for perturbations with no vertical structure, and are applicable mainly to the midplane of accretion discs interacting with a magnetosphere. Global 3D numerical studies of Rayleigh-Taylor instability induced accretion onto magnetized stars have been performed by Romanova, Kulkarni & Lovelace (2008) and Kulkarni & Romanova (2008), and show such small m instabilities in the disk midplane. The low- m oscillations at the magnetosphere-disc interface may be relevant to the high-frequency QPOs observed in some NS and BH X-ray binary systems (Li & Narayan, 2004; see Section 1 of Lai & Tsang for a critical review of various theoretical models), although to obtain the correct QPO frequencies for the BH systems, the disc inner radius must lie outside the inner-most stable circular orbit.

For the star-disc boundary model considered in this paper, the interface mode growth rates are much smaller than for the magnetospheric case, since the effective gravity now acts to stabilize the system, and the Rayleigh-Taylor instability is inactive. The modes discussed here are unstable due primarily to propagation through the corotation. With sufficiently steep disc density profile ($\Sigma \propto r^{-p}$ with $p > 3/2$), corotation absorption can also help to drive these modes, as studied previously by Tsang & Lai (2008) and Lai & Tsang (2008). Such modes may be responsible for the high-frequency (of order the Keplerian frequency at the stellar surface) dwarf nova oscillations observed in CVs, although oscillations with longer periods would require a different explanation.

APPENDIX: PLANE PARALLEL FLOW WITH A COMPRESSIBLE UPPER LAYER

Consider a system consisting of two fluids in the gravitational field $\mathbf{g} = -g\hat{\mathbf{z}}$. The upper fluid ($z > 0$) has density $\rho = \rho_+ e^{-z/H_z}$ (with $H_z = c_s^2/g$, where c_s is the sound speed) and horizontal velocity u_+ along the x-axis; the lower fluid ($z < 0$) is incompressible with density ρ_- and horizontal velocity u_- .

The linear perturbation equations for the upper fluid are

$$\frac{\partial}{\partial t}\delta\rho + \nabla \cdot (\rho\delta\mathbf{u} + \mathbf{u}\delta\rho) = 0 \quad (37)$$

$$\frac{\partial}{\partial t}\delta\mathbf{u} + (\mathbf{u} \cdot \nabla)\delta\mathbf{u} + (\delta\mathbf{u} \cdot \nabla)\mathbf{u}_0 = -\nabla\delta h \quad (38)$$

where $\delta h = \delta P/\rho$. For perturbations of the form $e^{ikx - i\omega t}$, these become

$$-i\tilde{\omega}\delta\rho + ik\rho\delta u_x + \frac{\partial}{\partial z}(\rho\delta u_z) = 0, \quad (39)$$

$$i\tilde{\omega}\delta u_z = \frac{\partial}{\partial z}\delta h, \quad (40)$$

$$i\tilde{\omega}\delta u_x = ik\delta h, \quad (41)$$

where $\tilde{\omega}_+ = \omega - ku_+$. Assuming the perturbation is isothermal, so that $\delta P = c_s^2\delta\rho$, we obtain

$$\delta h''(z) - \frac{1}{H_z}\delta h'(z) - (k^2 - \tilde{\omega}_+^2/c_s^2)\delta h(z) = 0. \quad (42)$$

The two independent solutions of equation (42)

$$\delta h \propto \exp\left[\frac{z}{2H_z}\left(1 \pm \sqrt{1 + 4H_z^2 k_z^2}\right)\right], \quad (43)$$

where $k_z^2 = (k^2 - \tilde{\omega}^2/c^2)$. Obviously, the physically relevant solution is

$$\delta h \propto \exp(-\tilde{k}z), \quad (44)$$

with $\tilde{k} = (\sqrt{1 + 4H_z^2 k_z^2} - 1)/2H_z$. This gives, by equation (40) the Eulerian pressure perturbation for the upper region:

$$\delta P_+ = -\frac{i\tilde{\omega}_+ \rho_+}{\tilde{k}} \delta u_{z+}. \quad (45)$$

For the lower region the fluid is an incompressible potential flow with $\delta \mathbf{u} = \nabla \delta \psi$ with $\delta \psi$ satisfying $\nabla^2 \delta \psi = 0$. For $z < 0$, the appropriate solution is

$$\delta \psi \propto \exp(kz). \quad (46)$$

This gives $\nabla(i\omega \delta \psi + \delta P_-/\rho_-) = 0$. The Eulerian pressure perturbation in the lower region ($z < 0$) is then:

$$\delta P_- = \frac{i\rho_- \tilde{\omega}_-}{k} \delta u_{z-}. \quad (47)$$

Matching the Lagrangian displacement and Lagrangian pressure perturbation across the boundary between the upper and lower regions we get

$$\frac{\tilde{\omega}_+^2 \rho_+}{\tilde{k}} + \rho_+ g = -\frac{\tilde{\omega}_-^2}{k} + \rho_- g, \quad (48)$$

which can be written as the quadratic:

$$\omega^2 - \left[\frac{\rho_+ \frac{k}{\tilde{k}} 2ku_+ + \rho_- 2ku_-}{\rho_+ \frac{k}{\tilde{k}} + \rho_-} \right] \omega + \frac{\rho_+ \frac{k}{\tilde{k}} k^2 u_+^2 + \rho_- k^2 u_-^2}{\rho_+ \frac{k}{\tilde{k}} + \rho_-} + g \frac{\rho_+ - \rho_-}{\rho_+ \frac{k}{\tilde{k}} + \rho_-} = 0. \quad (49)$$

where $\tilde{k}$ has a non trivial dependence on ω . This has a solution

$$\omega = \frac{k(\tilde{\rho}_+ u_+ + \rho_- u_-)}{\tilde{\rho}_+ + \rho_-} \pm \sqrt{-\frac{k^2(u_+ - u_-)\tilde{\rho}_+ \rho_-}{(\tilde{\rho}_+ + \rho_-)^2} - \frac{kg(\rho_+ - \rho_-)}{\tilde{\rho}_+ + \rho_-}} \quad (50)$$

where $\tilde{\rho}_+ = \rho_+ k/\tilde{k}$.
